45 **ABSTRACT**

46

47 An anonymous Bluetooth tracking system was deployed at the new Indianapolis  
48 International Airport from May 8 to June 2, 2009 to measure the time spent waiting in  
49 security screening lines, transiting the security screening checkpoint and walking to  
50 Concourse B. The maximum security checkpoint queue was observed to be on  
51 Monday mornings at approximately 0600 when it could take passengers up to twenty  
52 minutes to transit the security queue, screening process and walk to Concourse B.  
53 Depending upon the day of the week, this approach was demonstrated to sample  
54 between 5% and 6.8% of the passengers. This modest sample size provides a much  
55 more robust measurement of screening times than the current system of manually  
56 passing out time stamped cards as passengers enter the queue and collecting them  
57 when they pass through the magnetometer. The paper concludes by suggesting this  
58 system could provide important information to managers to more effectively allocate  
59 scarce resources on both a local and national level as well as providing the traveling  
60 public with information they need in order to know how much time they should  
61 allocate for transiting the security screening process at an airport.

62

63

64 **INTRODUCTION**

65 Obtaining both historical and real-time measurement of the time that it takes  
66 passengers to transit through both the queue and security screening process at  
67 airport checkpoints is of interest to a variety of stakeholders. For example,  
68 passengers would benefit from this information by allowing them to schedule  
69 appropriate slack time in their arrival at the airport. Also, managers responsible for  
70 staffing security checkpoints at a specific airport would have quantitative information  
71 to schedule personnel necessary to respond to daily, seasonal, and special  
72 event/holiday traffic. On a national scale, quantitative data for security screening  
73 transit time for major airports across the country would allow government officials to  
74 be more agile in responding to changes in airport origin-destination traffic patterns.  
75 Additional intangible benefits would also accrue to the travelling public by managers  
76 using quantitative tools to systematically reduce security checkpoint delays that occur  
77 due to shifting travel patterns.  
78

79

## 80 **CURRENT MEASUREMENT TECHNIQUES**

81 There are two primary techniques used for scheduling and assessing staffing  
82 resources at security checkpoints: checkpoint passenger counts and manual  
83 measurement of queue time. Figure 1 is an example of historical checkpoint  
84 passenger counts. This plot illustrates that most of the passengers pass through the  
85 security screening between 3am and 9pm, with the largest peak around 6am. These  
86 historical volumes can be augmented by airline reservation data to capture unusual  
87 demand patterns associated with holidays and large sporting events. However,  
88 these volumes only provide first order management tools because there are  
89 frequently differing demographics on different travel days and at different times. For  
90 example, there are differences in average passenger screening times between a  
91 business traveler and a family travelling on vacation. Screening times also vary due  
92 to factors such as amount of clothing worn by passengers in different region with  
93 different weather and temperature conditions.

94

95 Historically, this security volume data has been augmented by occasionally passing  
96 out time-stamped cards to passengers entering a security line queue and collecting  
97 them when they pass through the magnetometer. This technique is labor intensive  
98 for both the task of distributing/collecting the cards and the processing duties after  
99 they are collected. To obtain robust statistical estimates of average passenger  
100 transit, relatively large samples are necessary (1), but rarely collected for any  
101 substantive period. Consequently, there has been no development of planning level  
102 service time models that explicitly consider important factors such as passenger  
103 volume, regional characteristics, checkpoint layouts, and/or weather to model modern  
104 security checkpoints.

105

106 It would be desirable to implement real-time security transit time so that wait times  
107 could be directly measured for management and customer relations. The longer term  
108 benefit of deploying such systems would be a rich data set to develop accurate  
109 queuing models, such as have been developed for other transportation areas such as  
110 highway operations(2).

111

112

## 113 **MEASUREMENT TECHNOLOGIES**

114 There are a variety of technologies that can be used for real-time measurement of  
115 transit time in transportation systems, but in general they all fall into the category of  
116 matching unique identifiers between two points. For example, one of the oldest  
117 methods for estimating transit time between two points is to use two observers  
118 stationed at two different points along a route with each writing down license plates  
119 and the time that a vehicle pass a point on the highway (Figure 2a) (3, 4). After the  
120 data recording is completed and observers return to the office, the license plates are  
121 “matched” and the difference in observation times is recorded. This basic technique  
122 was first developed in the 1940’s, but has been enhanced over the years to include  
123 the use of computer image processing to automatically capture the license plate or  
124 other unique identifiers such as electronic ID numbers associated with toll tags or  
125 electromagnetic characteristics of vehicles.

126

127 Recently, agencies have extended these this technique further and begun using  
128 roadside devices to capture the discoverable unique 48 bit MAC addresses  
129 associated with discoverable Bluetooth devices in the vehicles such as cell phones  
130 (Figure 2b), GPS devices, mp3 players, hearing aids, and hands free devices (5).  
131 Not all vehicles have discoverable Bluetooth devices, but in general it has been  
132 reported that 5%-12% of the vehicles have one or more such discoverable devices  
133 on board (6). This sample size is large enough to develop very accurate estimates of  
134 segment travel time. Figure 3 illustrates the type of travel time information that is  
135 typically collected by highway agencies to identify periods of the day were long  
136 queues are developing and establishing proactive work zone management strategies  
137 and public communication procedures. The travel time plot shown in Figure 3 shows  
138 travel time measured over a 20 mile period in the Southbound direction of I-65 in  
139 Northwest Indiana. The increased traffic volume on Friday and Sunday show that the  
140 travel time over that 20 mile segment increases by over 1 hour during those periods.  
141 On Monday’s, the travel time through the construction zone increases by  
142 approximately 40 minutes during the afternoon period.

143

144

## 145 **INDIANAPOLIS AIRPORT CASE STUDY**

146 In an airport environment, the travel time measurement problem is essentially the  
147 same as highways, except it is the transit time of pedestrians (not vehicles) that is of  
148 interest and the distances are typically much shorter. Figure 4 illustrates the location  
149 of two reference points that can be used for measuring the transit time through a  
150 security queue, security screening, and pedestrian path to the sterile Concourse B  
151 area at Indianapolis International Airport.

152  
153 In this study, equipment similar to that used for roadside vehicle detection was placed  
154 at the locations shown in Figure 5 and Figure 6. However, this study used lower  
155 powered Class II Bluetooth radio receivers that had an approximate range of 10  
156 meters as opposed to 100 meters (Table 1). Figure 7 illustrates how these two  
157 monitoring locations can be used to capture the unique identifier “00:21:06:8C:7A” of  
158 an anonymous cell phone (Figure 2b) as the passenger carrying the cell phone  
159 enters the security line at 08:49, waits in the security screening line, is screened, and  
160 then enters Concourse B at 08:59.

161  
162 Figure 8 illustrates how the duration of this passenger transit time can be plotted  
163 throughout the day to characterize security line wait times. Of particular note is the  
164 contrast in the pattern of travel time shown in Figure 3 vs. the pattern of travel times  
165 shown in Figure 8. In the Interstate Highway example, most of the motorists join a  
166 single queue, except for a few that divert at exits and travel on adjacent local roads.  
167 However, in an airport, there are several “routes” through the security checkpoint. In  
168 the case of Concourse B at Indianapolis Airport at the time of the study, there were  
169 separate lines for

- 170 • Expert travelers
- 171 • Families
- 172 • The commercial service “Clear” (which has since ceased operation at IND)
- 173 • Airline crews

174 Furthermore, additional “noise” in the passenger security transit time plots for airports  
175 occurs because not all passengers take a direct, linear path through security to their  
176 gate. Therefore, there are some outlier travel times that are not representative of  
177 transit time through the security screening checkpoint. For example, from the pattern

178 of travel times plotted in Figure 8 it obvious that the security line transit times larger  
179 than 20 minutes after 0900 are not representative of a passenger that proceeds  
180 directly through the security screening area to Concourse B.

181

182 As a result, the travel times shown in Figure 8 require some judgment in interpreting  
183 typical transit times. However, it is fairly clear that the security transit time peaks  
184 around 0600 at about 20 minutes, and then tapers off to a maximum time of 10-15  
185 minutes throughout the rest of the day. The actual time waiting in the security line is  
186 considerably less because the plot shown in Figure 8 includes the time required for  
187 passengers to pass through security, reassemble their belongings, put their shoes  
188 on, and walk approximately 200 feet to pass the sensor on Concourse B (Figure 4).

189

190 Although daily security travel time plots like the one shown in Figure 8 are helpful,  
191 examining them in the context of passenger volumes can provide additional insight.  
192 Figure 9 shows the passenger volumes for Concourse B security screening during  
193 the period this pilot study was conducted and Figure 10 shows the corresponding  
194 travel time plots over the same period. A couple of trends are apparent when  
195 examining both of these plots:

- 196 • Figure 10 shows the peak security transit time is approximately 20 minutes  
197 and occurs on Monday May 11 during the morning peak. Figure 11 shows a  
198 detailed hourly comparison between the passenger count and the security  
199 transit time on May 11 with obvious correlation between the passenger count  
200 and security travel time.
- 201 • There are approximately 30% more passengers departing on Monday May 25  
202 (Memorial Day), but the typical security transit time is less than 15 minutes  
203 throughout the day.

204

205 Using the passenger counts and the number of uniquely matched Bluetooth MAC  
206 addresses, Figure 12 shows that between 5% and 6.8% of the passengers have  
207 discoverable Bluetooth devices on any given day. This is slightly lower than  
208 observed in a typical freeway traffic stream, but still large enough to very accurately  
209 characterize the transit time through an airport security checkpoint.

210

## 211 **PRIVACY ISSUES**

212 The MAC address shown in this research was for one of the paper co-authors. In a  
213 full deployment, consideration needs to be given to designing the data collection and  
214 destruction procedures. For example, the Indiana Department of Transportation has  
215 recorded over 1.4 million travel times for the construction work zone shown in Figure  
216 3, but has based all of their travel time calculations on MAC address that have had 3  
217 digits (octets) deleted. This is analogous to not recording some of the digits on a  
218 vehicle license plate. When such a clipping procedure is implemented at the data  
219 collection point, there is sufficient uniqueness in the data set to obtain very reliable  
220 travel time estimates, but not enough information to be able to prove the presence of  
221 a device with a specific MAC address at a particular time. More complex hashing  
222 algorithms could also be developed.

223

224 Furthermore, once a match has been made between the two checkpoints shown in  
225 Figure 4, there is no need for an airport to maintain the MAC address and it can be  
226 discarded after a few hours.

227

## 228 **CONCLUSION AND FUTURE RESEARCH**

229 This paper demonstrated that technology currently used to measure travel time along  
230 freeways and signalized arterials can be easily adapted to an airport environment to  
231 measure the transit time through a security checkpoint. The only technical  
232 modification was that Class II (instead of Class I) receivers were used to reduce the  
233 sampling radii of the Bluetooth monitoring devices. In comparison to highway  
234 environments, the 5-6.8% of passengers with discoverable Bluetooth devices on their  
235 persons was slightly lower, but large enough to accurately characterized passenger  
236 transit time through security.

237

238 This technology is currently deployed in highway environments for less than \$5000  
239 per installation. With the potential to collect continuous security time transit time  
240 data, this has the potential to provide managers with information to most effectively  
241 allocate scarce screening resources at both the local airport level and national level.

242

243 This pilot study was conducted at the new Indianapolis Airport Terminal that was  
244 opened in November 2008 with highly structured security checkpoints. This  
245 technology could be readily deployed at other airports throughout the country as well,  
246 but might require site specific use of directional antennas to accommodate nuances  
247 of older airport terminals.

248

249 Lastly, long term collection of i) passenger counts, ii) security transit times, and iii)  
250 security checkpoint configurations, and iv) security checkpoint staffing levels would  
251 allow the development of higher fidelity quantitative models relating passenger  
252 counts with security transit times (Figure 11).
